Epicatechin
Cocoa
Flavanols

A B S T R A C T

Background: Type 2 diabetes (T2D) and heart failure (HF) are associated with high levels of skeletal muscle (SkM) oxidative stress (OS). Health benefits attributed to flavonoids have been ascribed to antioxidation. However, for flavonoids with similar antioxidant potential, end-biological effects vary widely suggesting other mechanistic venues for reducing OS. Decreases in OS may follow the modulation of key regulatory pathways including antioxidant levels (e.g. glutathione) and enzymes such as mitochondrial superoxide dismutase (SOD2) and catalase.

Methods: We examined OS-related alterations in SkM in T2D/HF patients (as compared vs. healthy controls) and evaluated the effects of three-month treatment with (-)-epicatechin (Epi) rich cocoa (ERC). To evidence Epi as the mediator of the improved OS profile we examined the effects of pure Epi (vs. water) on SkM OS regulatory systems in a mouse model of insulin resistance and contrasted results vs. normal mice.

Results: There were severe alterations in OS regulatory systems in T2D/HF SkM as compared with healthy controls. Treatment with ERC induced recovery in glutathione levels and decreases in the nitrotyrosilation and carbonylation of proteins. With treatment, key transcriptional factors translocate into the nucleus leading to increases in SOD2 and catalase protein expression and activity levels. In insulin resistant mice, there were alterations in muscle OS and pure Epi replicated the beneficial effects of ERC found in humans.

Conclusions: Major perturbations in SkM OS can be reversed with ERC in T2D/HF patients. Epi likely mediates such effects and may provide an effective means to treat conditions associated with tissue OS.

1. Introduction

The consumption of modest amounts of cocoa products is associated with ~40% reduction in cardiometabolic risk [1]. Health benefits attributed to flavonoids have been mainly ascribed to direct antioxidation. Flavonoids, which are typically hydroxyl rich, are C15 compounds that comprise a very large family of plant derived secondary metabolites all of which have the structure C6–C3–C6. Examples include (-)-epicatechin and (+)-catechin. Their antioxidant potential is comparable given their very similar chemical composition and structure [2,3]. However, end-biological effects of flavonoids can vary widely, strongly suggesting other mechanistic venues [4]. Recent studies have reported on major biological effects of flavonoids at concentrations that are more closely aligned with receptor activation (nanomolar) vs. levels at which direct antioxidation (micromolar) or indirect (e.g. by impacting signaling systems) effects are likely to be significant [4].

The beneficial effect of cocoa on blood pressure [5] and on blood vessel function has been ascribed to epicatechin [6]. This assumption is supported by the results from bioavailability studies, which have shown that the bioavailability of catechin [7] and procyanidin dimer B2 [8] is comparably low. Further procyanidins are not bioavailable and do not contribute to circulating epicatechin pool [8]. It is possible
that the healthy effects of cocoa products rich in Epi that have been mainly attributed to direct antioxidation may follow the modulation of the expression and/or activity of oxidative stress (OS) regulatory systems. Tissue OS levels are modulated by multiple regulatory elements comprised of antioxidants (e.g., glutathione) and enzymes (e.g., superoxide dismutase, catalase) [9–11]. High levels of tissue OS can be recognized by the damage that it imposes on proteins, lipids and/or DNA. Patients suffering from type 2 diabetes mellitus (T2D) or heart failure (HF) have high levels of OS, which adversely impacts function in organs such as the heart, kidney, blood vessels and skeletal muscle (SkM). The coexistence of T2D and HF may further increase tissue OS [12,13].

In this study, we examined the effects of Epi rich cocoa (ERC) on T2D/HF patients or pure Epi in a mouse model of obesity/insulin resistance on SkM OS regulatory systems (Fig. 1). The approach used, explored the effects on known regulators of tissue OS (e.g. sirtuins) and evidenced their participation in different cellular compartments including the nucleus. We document major effects of ERC or Epi treatment on key regulatory system components that translate into notable decreases in OS. The actions exerted on OS regulatory elements likely contribute to the health benefits of cocoa and prominently account for the antioxidant effects of Epi.

2. Methods

Fig. 1 summarizes the experimental approach used for the analysis of human and animal samples.

2.1. Clinical trial

Five patients with stable New York Heart Association stages II and III HF and T2D, were recruited from the San Diego Veterans Administration Medical Center. Clinical characteristics of the patients are summarized in Table 1. All patients reported no adverse effects by treatment. Significant albeit, modest improvements were noted in HDL and a trend in BNP levels (P = 0.06), while no major changes were noted in cholesterol, LDL and triglycerides. There were no statistically significant changes in body weight, blood pressure or C-reactive protein (data not shown). All patients had standard therapy for HF and T2D and were on stable medical management at least 6 months previous to the study. No significant medication changes were made during the course of the study. This pilot open label protocol involved patients consuming Hershey’s Extra Dark 60% Cacao chocolate and cocoa beverages containing 18 g of natural cocoa powder for 3 months with a total of 100 mg (−)Epi content/day (half in the morning and half in the afternoon) with 390 kcal and 18 g of fat. Patients were instructed to refrain from consuming other chocolate products, supplements (e.g. vitamins) and otherwise follow a balanced, regular diet. Compliance was monitored every two weeks by telephone and by the use of written surveys. Patients underwent muscle biopsies from quadriceps femoris before and after ERC consumption. For comparison purposes, SkM biopsy samples from three healthy controls (age and sex matched) were obtained from the Medical Center using the same procedures as for patients. After collection, biopsy samples were frozen at −80 °C until used. The protocol was approved by the Institutional Review Board at the University of California, San Diego and all subjects gave informed consent.

2.2. Animal model

As an animal model of obesity and insulin resistance, two month old C57BL/6 mice were fed ad libitum with a high fat diet (HFD) for 16 weeks (rodent chow containing 60% kcal from fat, Research Diets, Inc.). Same age (i.e. six month old) C57BL/6 wild type mice fed normal chow were used for comparison purposes. Mice were treated by gavage for 15 days with 1 mg Epi/kg of body weight as described before [14].
were digitally quantified using ImageJ software (http://www.nih.gov).

2.8. Dot blot and nitrotyrosine detection

Five microliters containing 10 μg of total protein extract obtained from WB homogenates was placed on a vinyl membrane and dried. The membrane was incubated 1 h at room temperature in blocking solution. For nitrotyrosine detection the membrane was incubated with 1:2000 mouse monoclonal antibody against NO2Tyrr in blocking solution and developed using an enhanced chemiluminescence detection kit.

2.9. Immunoprecipitation (IP)

SKM (25 mg) was lysed with 200 μL of nondeaturing extraction buffer (0.5%, Triton X-100, 50 mM Tris-HCl, pH 7.4, 0.15 mM NaCl, 0.5 mM EDTA) and supplemented with protease and phosphatase inhibitor cocktails plus 2 mM/L Na3VO4 and 1 mM/L NaF. Homogenates were passed through an insulin syringe 3× and incubated on ice with shaking for 25 min and centrifuged (15 min, 4 °C) at 12,000 g. A total of 0.5 mg protein was precleared by adding 1 mg of normal rabbit IgG control and 20 μL protein A/G-agarose and mixed for 30 min (4 °C) with subsequent centrifugation at 12,000 g for 10 min at 4 °C. The supernatant was recovered and incubated at 4 °C under mild agitation for 3 h with 10 mL of IP antibody. Twenty microliters of protein A/G-sepharose was added, and the mixture was incubated overnight at 4 °C with shaking. The IP mixture was centrifuged at 12,000 g for 15 min at 4 °C, and the supernatant was recovered and stored at 4 °C for later analysis. The pellet was washed 3× with extraction buffer under shaking 15 min and centrifuged at 12,000 g for 15 min at 4 °C. The IP proteins in the pellet and those remaining in the supernatant were applied to a precast 4–15% sodium dodecyl sulfate–polyacrylamide gel electrophoresis for WB.

2.10. Nuclear protein extracts

Nuclear protein extracts were prepared using the nuclear protein isolation assay kit from FIVEphoton Biochemicals. Approximately 10 mg of SKM was used. Nuclear protein concentration was measured by Bradford and 40 μg of protein loaded into 4–15% precast gels and electrotansferred to nylon membranes for WB. TATA binding protein was used as a nuclear marker for these experiments (vs. GAPDH for cytoplasmic).

2.11. Chromatin immunoprecipitation (ChIP) and PCR assays

ChIP assays were performed using the Chromatin IP Kit (Agarose Beads) from Cell Signaling Co. Chromatin was subjected to IP with anti-PGC1α or anti-FOXO1 antibodies. Cross-linking was reversed and DNA was purified using MiniElute Spin Columns (QIAGEN) and used as template for PCR assays using the following primers: cattalase FOXO1-dependent binding element (−2160 to −1938), sense 5′-GGCTTCTGGTTTG CTTGTCCAG-3′, antisense 5′-ATACGATACGATCATGTTAGG-3′; Primers that amplifies the SP2 promoter region containing a FOXO1-dependent binding element at positions −1249 to −1033 (sense 5′-GCATCTTATAACTCCGGTC-3′, antisense 5′-GAGGACCGCTTCTGAGCTGG-3′), Amplification condition was 93 °C for 15 s, 64 °C for 30 s, and 72 °C for 25–30 cycles. The PCR products 222 bp and 216 bp for catalase and SOD2 respectively were analyzed in 2% agarose gel electrophoresis and stained with ethidium bromide. As a negative control, a 147 bp DNA fragment of the sarcospan gene was included using the following primers sense 5′-CAGTCAGCCCACTTCCTC-3′, antisense 5′-GGACAGCCAGAACAGTGATA-3′.

2.12. Data and statistical analysis

For all blot images, multiple exposures were obtained to ensure that the data obtained from computer assisted image analysis was within the linear range. Paired t-tests were used for comparison of before vs. after ERC effects. For comparisons of before and after data vs. healthy controls ANOVA (and a post-hoc Tukey’s analysis) was used. Data are expressed as mean ± SD. Statistical significance was defined when P < 0.05.
3. Results

3.1. Glutathione levels, carbonylation and nitrotyrosilation of proteins

At baseline, glutathione levels were significantly reduced by ~60% in patients as compared to healthy controls and were restored with ERC (Fig. 2A). The use of ERC also significantly stimulated protein levels of SOD2 (Fig. 3B upper panel and C). IP using a SOD2 antibody and immunoblotting against NO2Tyr, acetylated lysines and SIRT3 (Fig. 3B, lower panel) revealed an increased association between SIRT3 and SOD2 as well as significant reductions in SOD2 nitrotyrosilation and acetylation levels with ERC (Fig. 3B–E) (all densitometric values were normalized by S6RP). The levels of SOD2 activity were significantly reduced at baseline. ERC significantly increased SOD2 activity to levels higher than baseline and healthy controls (Fig. 4F).

3.2. SIRT3 and SOD2

We evaluated the effect that ERC had on SIRT3 protein levels as determined by WB. Results demonstrate a significant increase with treatment (Fig. 3A). The use of ERC also significantly stimulated protein levels of SOD2 (Fig. 3B upper panel and C). IP using a SOD2 antibody and immunoblotting against NO2Tyr, acetylated lysines and SIRT3 (Fig. 3B, lower panel) revealed an increased association between SIRT3 and SOD2 as well as significant reductions in SOD2 nitrotyrosilation and acetylation levels with ERC (Fig. 3B–E) (all densitometric values were normalized by S6RP). These changes were associated with significant increases in catalase activity to levels above baseline and healthy controls (Fig. 4D).

3.3. Catalase

With ERC, catalase protein abundance was significantly increased vs. baseline (Fig. 4A upper panel, B). Following catalase IP (Fig. 4A, lower panel) immunoblotting demonstrated decreased nitrotyrosilation relative to total catalase levels (Fig. 4C) (all densitometric values were normalized by S6RP). These changes were associated with significant increases in catalase activity to levels above baseline and healthy controls (Fig. 4D).

3.4. Changes in SIRT1, FOXO1 and PGC1α

Following IP with a SIRT1 antibody we evaluated the association of SIRT1, FOXO1 and PGC1α in SkM nuclei. The relative purity of SkM subcellular fractions is shown in Fig. 5A. Nuclear fraction “purity” was ascertained by high levels of TATA binding protein relative to GAPDH. ERC induced increases in nuclear protein levels of the total and active forms of SIRT1 (p-SIRT1) (Fig. 5B/C) and FOXO1 while reducing its acetylation (Fig. 5B/D). A similar pattern of changes was observed for total and acetylated PGC1α (Fig. 5B/E).

3.5. SOD2 and catalase promoter associated complexes

A ChIP assay was used to evidence chromatin associated proteins in SkM. ERC enhanced the association of PGC1α and FOXO1 with chromatin (Fig. 6A–C). Results show the enhanced association of deacetylated active forms of FOXO1 to PGC1α (Fig. 6A), PCR amplification of purified DNA fragments from the ChIP assay was also performed. ERC notably enhanced the binding of FOXO1 and PGC1α to the SOD2 and catalase promoters (Fig. 6D) (due to sample shortage this analysis was performed only in 4/5 patient samples) suggesting an increase in their transcriptional activity. PCR demonstrated no amplification of the sarcospan sequence (used as a negative control, data not shown).

4. Animal models

4.1. Changes in glutathione levels, carbonylation and nitrotyrosilation of proteins

To determine if Epi represents the active component of ERC, we compared the response of HFD mice to treatment and contrast results vs. controls. HFD mice yielded reduced SkM glutathione levels below those of controls. Significant increases were noted in control and HFD groups treated with Epi (Fig. 7A). Fig. 7B summarizes changes in SkM protein carbonylation levels, which increased in HFD animals and were significantly reduced in control and HFD groups with Epi. Changes in protein nitrotyrosilation levels as determined by dot blots are plotted in Fig. 7C. Results indicate that HFD increased nitrotyrosilation levels and Epi significantly reduced them.

4.2. Epicatechin-induced changes in SOD acetylation and activity levels

Results indicate that HFD leads to an increase in the ratio of acetylated/total SOD2 and Epi is able to restore to normal levels (Fig. 8A). As a consequence of these changes, SOD2 activity was significantly suppressed in HFD animals. Epi induced increases in control animals, while normalizing activity in HFD mice (Fig. 8B).

4.3. Epicatechin-induced changes in catalase nitrotyrosilation and activity levels

Results demonstrated increases in the ratio of nitrotyrosilation/total catalase in HFD animals and normalization with Epi (Fig. 8C). Catalase activity levels followed the same pattern as noted for SOD2 (Fig. 8D).

5. Discussion

Alterations in mitochondrial function can lead to increases in the production or “leakage” of reactive oxygen species (ROS) particularly superoxide anion. Sustained increases in ROS can overwhelm SOD and catalase levels or block their activity, leading to OS and, in consequence to tissue damage. We previously reported evidence for severe detrimental changes in SkM mitochondria structure in T2D/HF patients [15]. We also demonstrated that 3 month treatment with ERC led to notable improvements in SkM mitochondrial cristae abundance and indicators of biogenesis. We hypothesized that the recovery of mitochondrial structure observed with treatment in T2D/HF patients would lead to decreases in SkM oxidative stress.

A depletion of glutathione has been documented in T2D and HF SkM [16]. Increases in SkM glutathione can be triggered in T2D patients with thiazolidinedione treatment and this is coupled with improved muscle function [17]. In HF patients, the use of AT1 receptor blockers (by blocking NADPH-oxidases) can increase glutathione and this may, partly explain their beneficial effects [18]. Fig. 2 results demonstrate that at baseline, SkM glutathione levels were reduced.

![Fig. 2. Modulation of SkM oxidative stress markers by ERC in T2D/HF patients before and after treatment. (A) Changes in glutathione levels vs. control. (B) Summary of changes observed in carbonylation (DNP) and nitrotyrosine residue formation (NO2Tyr) vs. control. (Control n = 3, patients n = 4, *P < 0.05 vs. before, # vs. control).](image-url)
by ~60% in T2D/HF patients and were restored to control levels with ERC. To our knowledge, this is the first study documenting, in human SkM, this type of response to flavonoids. However, in a rodent model of liver injury or in cultured HepG2 and Caco-2 cells, cocoa extracts can preserve glutathione levels [19–21]. We have also demonstrated the preservation of glutathione levels by Epi in ischemic myocardium [22].

Excess levels of carbonylation and nitrotyrosilation have been documented in SkM of T2D and HF patients [23]. Drugs used to treat T2D patients such as metformin, have been associated with reductions in this type of deleterious amino-acid residue modification [24]. Fig. 2 results show that protein carbonylation and nitrotyrosilation levels were significantly increased at baseline (vs. controls) and were normalized (carbonylation) or significantly reduced (nitrotyrosilation) by ERC. Whereas no studies have reported on the effects of cocoa on similar endpoints in human tissues, flavonoid supplementation reduces protein carbonyls in the blood of subjects undergoing intense exercise [25].

An early ROS molecule (from the multiple types generated) whose excess can lead to OS is superoxide \((O_2^{−})\). Important pathways that modulate its excess include SOD, which generate hydrogen peroxide, as well as catalase, which convert hydrogen peroxide into water and molecular oxygen [9,10]. Reductions in the activity of these enzymes are known to be detrimental to organ function [26]. Conversely, transgenic approaches have demonstrated that their upregulation can be protective [27]. SIRT3 is an enzyme that positively regulates mitochondrial SOD2 activity via its deacetylation. So far, only endurance exercise training in old, sedentary subjects has reported to stimulate SkM SIRT3 protein levels [28]. Fig. 3 results demonstrate that ERC stimulates increases in SIRT3 and SOD2 protein levels and their physical association. Secondary to this enhanced association; significant reductions in SOD2 acetylation and nitrotyrosilation were

(A) Changes detected in SIRT3 protein levels as observed by Westerns (normalized with S6RP levels). (B, upper panel) Changes in total SOD2 levels as observed by Westerns and, (C) their quantification. (B, bottom panel) Changes in SIRT3 protein levels following SOD2 based IP and their complexing to SOD2. (D) Decreases observed in SOD2 acetylation and, (E) nitrotyrosine residue formation. (F) Changes observed in SOD2 activity levels vs. control. (Control n = 3, patients n = 5, *P < 0.05 vs. before, # vs. control).
observed, leading to enhanced enzymatic activity. Of interest is that increases in SOD activity also decrease the chance of O$_2^\cdot{}$ to react with high levels of nitric oxide as observed with T2D and HF to yield excess peroxynitrite and therefore, excess nitrotyrosilation. ERC also induced significant increases in catalase protein levels and a decrease in nitrotyrosilation leading to increases in catalase activity.

(E) Changes observed in the ratio of acetylated/total PGC1α levels. (n = 5, *P < 0.05 vs. before).
In spite of many studies reporting on the apparent antioxidant effects of cocoa products in humans, most only report on blood markers with no specific reference to actions on SOD or catalase.
[29]. However, in rats, it has been reported that cocoa intake stimulates thymus SOD and catalase activity [30]. There are several important regulators of SOD2 and catalase transcription that include amongst others, the deacetylase SIRT1, FOXO1 and PGC1α. When in an “inactive” state, the regulators dephosphorylated SIRT1, acetylated FOXO1 and PGC1α are localized mainly in cytoplasm. Upon stimulation, these regulators translocate into the nucleus, SIRT1 becomes phosphorylated and deacetylates FOXO1 and PGC1α, which then form an “active” complex [31]. This complex can then bind to the promoter region of DNA and activate the transcription of genes such as SOD2 and catalase. The documentation of such events (Figs. 5, 6) would identify the mechanisms underlying ERC effects. With ERC treatment, the relative levels of nuclear total SIRT1 and its active form phospho-SIRT1 increased. The total levels of FOXO1 protein increased while its inactive acetylated form decreased, and a similar pattern of changes was observed for PGC1α. Thus, ERC is capable of stimulating the nuclear translocation and activation of known transcriptional modulators of SOD2 and catalase.

To further document the functionality of this complex, the verification of its association with DNA promoter regions was necessary. ChIP assay results (Fig. 6) demonstrate that there is an enhanced association of PGC1α and FOXO1 to chromatin after treatment with ERC. As per PCR results, ERC increased the binding of the transcription factors to the SOD2 and catalase promoters, an event that likely explains increases in protein levels. There is precedent for studies that have examined the capacity of flavonoids to alter the transcription of genes involved in OS regulatory systems [32,33]. However, these studies have mostly relied on the use of indirect reporter systems.

To our knowledge this is the first time that a systematic documentation of mechanistic events is pursued in human SKM so as to explain the modulation of OS regulatory systems by an intervention such as ERC. Only one similar study has been performed in HF patients where the effects of exercise were examined [34]. Six months of exercise training increases SKM catalase activity (while not altering mRNA or protein levels) and reduces lipid peroxidation and nitrotyrosine residue formation while no changes in SODs were observed [34].

As cocoa products contain many components, which can influence the above measured endpoints, an animal model of obesity and insulin resistance was used to examine the unique effects of Epi on representative OS related endpoints. HFD reduced SKM glutathione levels below those of controls (Fig. 7). Significant increases were detected in control and HFD groups treated with Epi. Protein carbonylation levels increased in HFD animals and were reduced with Epi treatment. Changes in protein nitrosylation indicate that a HFD increased their levels and Epi significantly reduced them. HFD also leads to an increase in the ratio of acetylated/total SOD2 and normalization with Epi with parallel changes in SOD2 activity (Fig. 8). Comparable observations were noted for catalase. Altogether, results derived from animal studies strongly suggest that Epi can be ascribed as a likely major mediator of effects in ERC treated patients. Our results are in general agreement with those published by Si et al., where the use of Epi led to beneficial effects in diabetic (db/db) mouse SKM contractile function, liver fat deposition, glutathione levels or protein levels and reduces lipid peroxidation and nitrotyrosine residue formation while no changes in SODs were observed [34].

The use of compounds with antioxidant properties typically given at “high” doses such as vitamins, has largely failed to mitigate disease progression. Furthermore, the putative beneficial effects of antioxidants on SKM function and thus, improved exercise performance, have not been completely established and the results are contradictory [36]. Therefore, “direct” antioxidation (i.e. ROS scavenging) as a means to improve organ function remains at best, unproven. Flavonoids (which act as ROS scavengers) reduce tissue OS and are known to yield healthy effects. However, at low doses direct antioxidation does not appear to explain these effects. The body of mechanistic results in human SKM obtained in this study, and validated by investigations in animals, indicates that effective reductions in SkM OS follow the modulation of key regulatory systems by Epi.

Limitations of this pilot study include the lack of measurements of Epi levels in the muscle, small number of subjects studied and the absence of proper controls (including HF or T2D only patients). Nonetheless, given the consistency and magnitude of “recovery” effects exerted by ERC in all patients, results suggest a unique potential to improve muscle metabolism. However, we cannot rule out the possibility that other cocoa bioactive agents may have played a role in the responses observed.

In conclusion, the use of ERC or Epi appears to modify tissue OS in a manner consistent (given the doses used) with the modulation of relevant regulatory systems. Thus, ERC or Epi deserve consideration as potential effective modulators of tissue OS to be evaluated in future controlled clinical trials for diseases where metabolic dysregulation represents an underlying mechanism.
